SILVER CONTAINING COPPER ALLOY

(Signature of Person Mailing paper or fee.)

CROSS REFERENCE TO RELATED PATENT APPLICATION

This patent application claims priority to United
5 States Provisional Patent Application Serial Number
60/224,054 that was filed on August 9, 2000. The
subject matter of that provisional patent application is
incorporated by reference in its entirety herein.

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to a silver containing
copper alloy. More particularly, the inclusion of a
controlled amount of silver in a copper alloy that
15 further contains chromium, titanium and silicon results
in improved resistance to stress relaxation and improved
isotropic bend properties without a detrimental effect
on either yield strength or electrical conductivity.

2. Description of Related Art

Copper alloys are formed into numerous products
that take advantage of the high electrical conductivity
and/or high thermal conductivity of the alloys. A
partial list of such products includes electrical
25 connectors, leadframes, wires, tubes, foils and powders
that may be compacted into products. One type of
electrical connector is a box-like structure formed by
stamping a predefined shape from a copper alloy strip
and then bending the stamped part to form the connector.
30 It is necessary for the connector to have high strength

and high electrical conductivity. In addition, the connector should have a minimal reduction in normal force as a function of time and temperature exposure, commonly referred to as resistance to stress relaxation.

5 Properties important for an electrical connector include yield strength, bend formability, resistance to stress relaxation, modulus of elasticity, ultimate tensile strength and electrical conductivity.

10 Target values for these properties and relative importance of the properties are dependent on the intended application of products manufactured from the subject copper alloys. The following property descriptions are generic for many intended applications, but the target values are specific for under the hood
15 automotive applications.

20 The yield strength is the stress at which a material exhibits a specified deviation, typically an offset of 0.2%, from proportionality of stress and strain. This is indicative of the stress at which plastic deformation becomes dominant with respect to elastic deformation. It is desirable for copper alloys utilized as connectors to have a yield strength on the order of 80 ksi, that is approximately 550 MPa.

25 Stress relaxation becomes apparent when an external stress is applied to a metallic strip in service, such as when the strip is loaded after having been bent into a connector. The metal reacts by developing an equal and opposite internal stress. If the metal is held in a strained position, the internal stress will decrease as
30 a function of both time and temperature. This

phenomenon occurs because of the conversion of elastic strain in the metal to plastic, or permanent strain, by microplastic flow.

5 Copper based electrical connectors must maintain above a threshold contact force on a mating member for prolonged times for good electrical connection. Stress relaxation reduces the contact force to below the threshold leading to an open circuit. It is a target for a copper alloy for connector applications to
10 maintain at least 90% of the initial stress when exposed to a temperature of 150°C for 1000 hours and to maintain 85% of the initial stress when exposed to a temperature of 200°C for 1000 hours.

15 The modulus of elasticity, also known as Young's modulus, is a measure of the rigidity or stiffness of a metal and is the ratio of stress to corresponding strain in the elastic region. Since the modulus of elasticity is a measure of the stiffness of a material, a high modulus, on the order of 150 GPa is desirable.

20 Bendability determines the minimum bend radius (MBR) which identifies how severe a bend may be formed in a metallic strip without fracture along an outside radius of the bend. The MBR is an important property for connectors where different shapes are to be formed
25 with bends at various angles.

Bend formability may be expressed as, MBR/t , where t is the thickness of the metal strip. MBR/t is a ratio of the minimum radius of curvature of a mandrel about which the metallic strip can be bent without failure.

30 The "mandrel" test is specified in ASTM (American

5)

10

11

20

25

For a given metal sample, both methods give quantifiable bendability results and either method may be utilized to determine relative bendability.

5 The ultimate tensile strength is a ratio of the maximum load a strip withstands until failure during a tensile test expressed as a ratio of the maximum load to the cross-sectional area of the strip. It is desirable for the ultimate tensile strength to be about 85 - 90 ksi, that is approximately 585 - 620 MPa.

10 Electrical conductivity is expressed in % IACS (International Annealed Copper Standard) in which unalloyed copper is defined as having an electrical conductivity of 100% IACS at 20°C. It is desirable for copper alloys for high performance electrical connectors
15 to have an electrical conductivity of at least 75% IACS. More preferably, the electrical conductivity is 80% IACS or higher.

20 One copper alloy that approaches the desired properties is designated by the Copper Development Association, New York, NY, as C18600. C18600 is an iron containing copper-chromium-zirconium alloy and is disclosed in US Patent No. 5,370,840 to Caron, et al that is incorporated by reference in its entirety
25 herein. C18600 has a nominal composition by weight of 0.3% chromium, 0.2% zirconium, 0.5% iron, 0.2% titanium and the balance copper and inevitable impurities.

Throughout this patent application, all percentages are expressed as weight percent unless otherwise noted.

30 Mechanical and electrical properties of copper alloys are highly dependent on processing. If C18600 is

subjected to an aging anneal, a 33% cold roll and a relief anneal, the alloy achieves as nominal properties: an electrical conductivity of 73% IACS; a yield strength of 90 ksi; a 90° MBR/t of 1.2 in the good way and 3.5 in the bad way utilizing the mandrel method("roller bend" method); and a 20% loss in stress when subjected to 200°C for 1000 hours.

US Patent Number 4,678,637 to Duerrschnabel et al discloses a copper alloy containing additions of chromium, titanium and silicon and is incorporated by reference in its entirety herein. This alloy, designated by the CDA as C18070, has a nominal composition of 0.28% chromium, 0.06% titanium, 0.04% silicon and the balance copper and unavoidable impurities. When processed by hot rolling, quench and cold rolling interspersed with one or two intermediate bell anneals, the alloy achieves as nominal properties: an electrical conductivity of 86% IACS; a yield strength of 72 ksi (496 MPa), a 90° MBR of 1.6t in the good way and 2.6t in the bad way; and a loss of 32% of the stress when subjected to 200°C for 1000 hours.

DE 196 00 864 C2 by Wieland-Werke AG, discloses an alloy containing 0.1%-0.5% chromium, 0.01%-0.25% titanium, 0.01%-0.1% silicon, 0.02%-0.8% magnesium with the balance being copper and inevitable impurities. The magnesium addition is disclosed as improving the resistance of the alloy to stress relaxation.

A small addition of silver, on the order of up to 25 troy ounces per ton avoirdupois (.085 weight percent), enables cold worked copper to maintain its

strength at temperatures of up to about 400°C as disclosed in Silver-Bearing Copper by Finlay, 1968. One silver-containing copper alloy is designated by the CDA as copper alloy C15500. C15500 contains 0.027-0.10% silver, 0.04-0.08% phosphorous, 0.08-0.13% magnesium and the balance is copper and unavoidable impurities. The alloy is reported in the ASM Handbook as having an electrical conductivity of 90% IACS in an annealed condition, a yield strength of 72 ksi (496 MPa) in the spring temper. Bend formability and resistance to stress relaxation are not reported.

While the copper alloys described above achieve some of the desired properties for connectors, there remains a need for an improved copper alloy that comes closer to the target requirements and further, there remains a need to characterize a copper alloy utilizing a holistic system that integrates multiple customer identified desired properties into a single performance indicator.

SUMMARY OF THE INVENTION

Accordingly, it is an object of the invention to provide a copper base alloy that is particularly suited for electrical connector applications. It is a feature of the invention that this copper base alloy contains chromium, titanium and silver. Yet another feature of the invention is that iron and tin may be added to promote grain refinement and increase strength. Still another feature of the invention is to maximize desired electrical and mechanical properties by processing of

the alloy including the steps of solution anneal,
quench, cold roll and age. Still a further feature of
the invention is that a holistic approach to alloy
properties is utilized to integrate multiple alloy
5 properties by way of factors weighted by customer
derived rankings for specific connector applications.

It is an advantage of the invention that the alloy
of the invention may be processed to have a yield
strength in excess of 80 ksi (550 MPa) and an electrical
10 conductivity in excess of 80% IACS making the alloy
particularly useful for forming into electrical
connectors for both automotive and multimedia
applications. Among the advantageous properties of the
alloy of the invention are an enhanced resistance to
15 stress relaxation at elevated temperatures of up to
200°C. A still further advantage is that a strip of
metal formed from the alloy has substantially isotropic
bend formability and excellent stampability making it
particularly useful for forming into box-type
20 connectors.

In accordance with the invention, there is provided
a copper alloy that consists essentially of, by weight,
from 0.15% to 0.7% of chromium, from 0.005% to 0.3% of
silver, from 0.01% to 0.15% of titanium, from 0.01% to
25 0.10% of silicon, up to 0.2% of iron, up to 0.5% of tin,
and the balance is copper and inevitable impurities.

In accordance with the invention there is provided
a process for forming a copper alloy having high
electrical conductivity, good resistance to stress
30 relaxation and isotropic bend properties. This process

includes the steps of casting a copper alloy that contains, by weight, from 0.15% to 0.7% of chromium, additional desired alloying additions, and the balance is copper and inevitable impurities. This copper alloy is formed into a strip that is solution annealed, by a strip anneal process, at a temperature of from 850°C to 1030°C for from 5 seconds to 10 minutes. A preferred strip anneal time is from 10 seconds to 5 minutes. The strip is then quenched from a temperature of at least 850°C to a temperature of less than 500°C in at most 10 seconds. The quenched strip is then cold rolled to a reduction of from 40% to 99% in thickness and then annealed at a temperature of between 350°C and 550°C for from one hour to 10 hours.

The above stated objects, features and advantages will become more apparent from the specification and drawings that follow.

IN THE DRAWINGS

Figure 1 is a flow chart of processing steps for the manufacture of strip from the copper alloy of the invention.

Figure 2 is a flow chart of processing steps for the manufacture of wire or rod from the copper alloy of the invention.

Figures 3 and 4 graphically illustrate recrystallized grain size for two related alloys of the invention as a function of solution annealing temperature and solution annealing time.

DETAILED DESCRIPTION

The alloy of the invention is particularly suited for under the hood automotive applications where it may be subject to elevated ambient temperatures as well as relatively high electrical currents generating I²R heating. In addition, the alloy is useful for multimedia applications, such as computers or telephones, where the service temperature is lower, typically on the order of 100°C maximum, and signals of relatively low electrical currents are carried.

The alloy of the invention consists essentially of:
from 0.15% to 0.7% chromium,
from 0.005% to 0.3% silver,
from 0.01% to 0.15% titanium,
from 0.01% to 0.10% silicon,
up to 0.2% iron,
up to 0.5% tin, and
the balance is copper and inevitable impurities.

A more preferred alloy range is:
from 0.25%-0.60% chromium,
from 0.015%-0.2% silver,
from 0.01%-0.10% titanium,
from 0.01%-0.10% silicon,
less than 0.1% iron,
up to 0.25% tin, and
the balance is copper and inevitable impurities.

A most preferred alloy composition is:

from 0.3%-0.55% chromium,

from 0.08%-0.13% silver,

from 0.02%-0.065% titanium,

5 from 0.02%-0.08% silicon,

0.03%-0.09% iron,

less than 0.05% tin, and

the balance is copper and inevitable impurities.

10 If high strength is of particularly high relative importance, then the titanium content should be 0.05% or higher. If high electrical conductivity is of particularly high relative importance, then the titanium content should be 0.065% or less.

15 Chromium - Chromium particles precipitate during aging anneals thereby providing age-hardening and a concomitant conductivity increase. It is also believed that the chromium precipitate stabilizes the alloy microstructure by retarding grain growth through second
20 phase pinning of grain boundaries. A minimum of 0.15%, by weight, of chromium is required to achieve these beneficial results.

When the chromium content exceeds 0.7%, the maximum solid solubility limit of chromium in the copper alloy
25 is approached and a coarse second phase precipitate develops. The coarse precipitate detrimentally affects both the surface quality and plating characteristics of the copper alloy without a further increase in the strength of the alloy. It is further believed that an

excess of chromium detrimentally impacts
recrystallization.

Silver - Silver promotes isotropic bend properties
thereby improving the utility of the alloy for
5 electrical connector applications. In addition, silver
increases strength, particularly when the chromium
content is at the low end, 0.3% or less, of the
specified ranges. When the alloy is in the aged
condition, the silver addition improves resistance to
10 elevated temperature stress relaxation.

When the silver content is less than 0.005%, the
beneficial effects are not fully realized. When the
silver content exceeds 0.3%, the increased cost due to
the presence of silver outweighs the benefits of its
15 inclusion.

Titanium - Titanium enhances stress relaxation
resistance and increases the alloy strength. Below
0.01% titanium, these beneficial effects are not
achieved. Excess titanium has a detrimental effect on
20 electrical conductivity of the alloy, probably more so
than any of the other alloying elements. To achieve an
electrical conductivity of at least 80% IACS, the
titanium content should be maintained at 0.065% or less.
To achieve a high strength, the titanium content should
25 be maintained at 0.05% or more.

Silicon - Silicon enhances stress relaxation
resistance and alloy strength. When the silicon content
is less than 0.01%, the beneficial effect is not
achieved. When the silicon content exceeds 0.1%, a loss

in electrical conductivity outweighs any gain in stress relaxation resistance.

5 Iron - Iron is an optional addition that increases the strength of the alloy and also enhances grain refinement, in both the as-cast and as-processed condition. The grain refinement improves bend formability. However, an excess of iron unduly decreases electrical conductivity. An electrical conductivity of 80% IACS is a desirable consideration, and therefore the iron should be restricted to below 0.1% in accordance with the most preferred alloy composition.

10 When present, the iron to titanium ratio, by weight, is preferably between 0.7:1 and 2.5:1, and more preferably between 0.9:1 and 1.7:1 and most preferably about 1.3:1. For some embodiments, the iron to tin ratio, by weight, is preferably between 0.9:1 and 1.1:1 and more preferably about 1:1.

15 Tin - Tin is an optional addition that increases the strength of the alloy, but if present in an excessive amount reduces electrical conductivity and also appears to promote stress relaxation. Accordingly, there should be less than 0.5% by weight tin present in the alloy and preferably less than 0.05% tin in the alloy when an electrical conductivity of 80% IACS is required.

20 Other additions - Other elements may be present in the alloy of the invention to achieve desired property enhancements without significantly reducing desirable properties such as bend formability, resistance to

25

30

stress relaxation or electrical conductivity. The total content of these other elements is, for the most part, less than 1% and preferably less 0.5%. Exceptions to this generality are recited below.

5 Cobalt may be added as a 1:1, by weight, substitute for iron.

10 Magnesium may be added to improve solderability and solder adhesion. Magnesium is also effective to enhance cleaning of the alloy surface during processing. A preferred magnesium content is from about 0.05% to about 0.2%. Magnesium may also improve the stress relaxation characteristics of the alloy.

15 Machinability, without a significant decrease in electrical conductivity, can be enhanced by additions of sulfur, selenium, tellurium, lead or bismuth. These machinability enhancing additions form a separate phase within the alloy and do not reduce electrical conductivity. Preferred contents are up to 3% for lead, from about 0.2% to about 0.5% for sulfur and from about 20 0.4% to 0.7% for tellurium.

De-oxidizers can be added in preferred amounts of from about 0.001% to about 0.1%. Suitable de-oxidizers include boron, lithium, beryllium, calcium and rare earth metals either individually or as mischmetal.

25 Boron, that forms borides, is beneficial as it also increases the alloy strength. Magnesium, recited hereinabove, is also effective as a deoxidizer.

Additions which increase strength, with a reduction in electrical conductivity, including aluminum and 30 nickel, should be present in amounts of less than 0.1%.

Zirconium has a propensity to combine with silicon and form coarse particles of zirconium silicide. Therefore, it is preferred that the alloy be essentially zirconium free, that is zirconium in impurity amounts
5 only.

The processing of the alloy of the invention has a significant impact on the finished gauge alloy properties. Figure 1 illustrates in block diagram a sequence of processing steps to achieve the yield
10 strength, bend formability, resistance to stress relaxation, modulus of elasticity, ultimate tensile strength and electrical conductivity desired for the subject copper alloy. These processing steps are believed beneficial for any chromium containing copper
15 alloy.

The alloy is initially cast 10 by any suitable process. For example, cathode copper may be melted at a temperature of approximately 1200°C in a crucible or a melt furnace with a charcoal cover. Chromium, and as
20 desired, the other alloying elements of titanium, silicon, silver and iron are then added to the melt in the form of appropriate master alloys for a casting of a desired composition. The casting may be via a continuous process, such as strip casting or belt
25 casting, in which the casting leaves the strip or belt at a thickness suitable for cold rolling 12 prior to solution annealing 14. This casting thickness is preferably from about 0.4 inch to 1 inch and it is then cold rolled to a nominal thickness of about 0.045 inch.

Alternatively, the alloy may be cast 10' as a rectangular ingot and broken down into strip by hot rolling 16. Typically, hot rolling will be at a temperature of between 750°C and 1030°C and used to
5 reduce the thickness of the ingot to somewhat above the solution anneal thickness. Hot rolling may be in multiple passes and generally used to form a strip having a thickness greater than that desired for solution annealing.

10 While processing is described in terms of a copper alloy strip with working by hot and cold rolling, the copper alloys of the invention may also be formed into rods, wires or tubes in which instance, the working would more likely be in the form of drawing or
15 extrusion.

Following hot rolling 16, the strip is water quenched and then trimmed and milled to remove any oxide coatings. The strip is then cold rolled 12 to solution anneal 14 gauge. Cold rolling 12 may be in a single
20 pass or multiple passes with intermediate anneals if necessary. An intermediate anneal at a temperature of from about 400°C to 550°C for from about four hours to eight hours yielded, at the end of the process, a higher strength alloy with fine grains, on the order of 10
25 microns, and a homogenous structure. If the intermediate anneal temperature approaches full homogenization, the alloy at the end of the process has lower strength and coarse grain stringers. Omitting the intermediate anneal results in an alloy at the end of
30 processing with a grain size in the 25 micron to 30

micron range. To enhance the recrystallized grain structure, it is preferred that the cold rolling step impart the strip with a degree of cold work, such as a 25% - 90% reduction in thickness.

5 The alloy is solution annealed 14 at a time and temperature effective to achieve full recrystallization without excessive grain growth. Preferably, the maximum grain size is maintained at 20 microns or less. More preferably, the maximum grain size is 15 microns or
10 less. The annealing time and temperature should further be selected to be effective to achieve microstructural homogeneity. Thus, if the annealing time or temperature is too low, hardness and microstructural deviations from one portion of the strip to the other are obtained
15 leading to non-isotropic bend properties. Excessive annealing time or temperature leads to undue grain growth and poor bend formability. As a broad range, the solution anneal 14 should be a strip anneal at a temperature of from 850°C to 1030°C for from 10 seconds
20 to 15 minutes. More preferably, the solution anneal 14 is at a temperature of from 900°C to 1000°C for from 15 seconds to ten minutes and most preferably from 930°C to 980°C for from 20 seconds to five minutes.

25 Figure 3 graphically illustrates the effect of solution annealing (SA) time and temperature on the recrystallization and grain growth for a copper alloy having 0.40% chromium. The reported values, such as 10-15µm, are grain size. At a temperature of 950°C, recrystallization without undue grain growth is achieved

at an annealing time of from about 17 seconds to about 35 seconds. At less than 17 seconds there is limited recrystallization. In excess of 35 seconds, the alloy is fully recrystallized but grain sizes of between 20 and 25 microns are formed and when the time exceeds about 40 seconds, rapid grain growth with grains in the 30 micron up to 100 micron range are obtained.

Figure 4 graphically illustrates the effect of solution annealing time to temperature when the alloy contains 0.54% chromium and demonstrates how increasing the chromium content broadens the acceptable range of annealing time and temperature. Recrystallization with a grain size of 10 to 15 microns is achievable in this instance at 950°C with times of from about 7 seconds up to about 45 seconds. However, while grain size is very well controlled, undissolved chromium particles become larger degrading alloy properties.

Referring back to Figure 1, the solution annealed 14 alloy is next quenched 18 to retain microstructural homogeneity. Quenching should take the alloy temperature from the solution anneal temperature, minimum 850°C and preferably in excess of 900°C, to below 500°C in 20 seconds or less. More preferably, the quench rate is from 900°C to less than 500°C in 10 seconds or less.

While multiple solutionization anneals 14 effective for recrystallization may be utilized, it is preferred that there is a single solution anneal effective for recrystallization.

Following quenching 18, the alloy is cold rolled 20 to a 40% to 80%, by thickness, reduction for strip or sheet. For foil, a cold roll reduction in excess of 90%, or preferably up to 99%, in thickness, is 5 preferred. Preferably, the strip or sheet cold rolled reduction is from 50% to 70%, by thickness, and effected with one or more passes through the rolling mill to generate a heavily cold worked strip.

The alloy is next given an aging heat treatment 22. 10 The aging heat treatment 22 may be in one step, or preferably is in two steps. It has been found that step aging results in higher strength and electrical conductivity and it is believed that bend formability may also be improved by the step aging. The first aging 15 step, and only aging step if done in a single step, is at a temperature of from about 350°C to about 550°C for from one to ten hours. Preferably, this first aging step 22 is at a temperature of from 400°C to 500°C for from one to three hours.

20 If the age anneal is done in multiple steps, the second step anneal 24 is at a temperature of from about 300°C to about 450°C for from one to twenty hours leading to increased electrical conductivity without a loss in strength. Preferably, the second step aging 24 is at a 25 temperature of from about 350°C to about 420°C for from five to seven hours.

The alloy may be used in the age annealed condition when enhanced resistance to stress relaxation is required, for example, in automotive applications.

30 Following the aging anneal, the alloy has a yield

strength of about 68 ksi (470 MPa) and an electrical conductivity of about 80% IACS. If still higher strengths are required, additional processing steps may follow the age anneal step 22 or 24.

5 The age annealed copper alloy strip is cold rolled 26 to a final gauge thickness, typically on the order of 0.25 mm to 0.35 mm, although it is a target for future connectors to have a thickness on the order of 0.15 mm (0.006 inch) or less. The thin strip material, under
10 about 0.006 inch, is also useful as a copper alloy foil product. Generally, the cold rolling 26 will be in one or more passes through a rolling mill with a reduction of between 10% and 50%, in thickness.

15 Following cold roll 26, there may be a stress relief anneal 28 at a temperature of between 200°C and 500°C for from 10 seconds to 10 hours. Preferably, the stress relief anneal 28 is at a temperature of between 250°C and 350°C for from 1 hour to 3 hours.

20 Figure 2 illustrates in block diagram a process flow particularly suited for the manufacture of wire and rod. The copper alloy of the invention is cast 30 by any suitable process and extruded 32 to form a rod with a desired cross-sectional shape, preferably the cross-sectional shape is circular. The hot extrusion is at a
25 temperature of between 700°C and 1030°C and preferably at a temperature of between 930°C and 1020°C.

30 The extruded rod is quenched 34 and then cold drawn (or cold extruded) 36 to a reduction in diameter of up to 98%. The drawn rod is then annealed 38 at a temperature of from 350°C to 900°C for from 1 minute up

to 6 hours. The sequence of cold draw 36 and anneal 38 may be repeated one or more additional times and then cold drawn (or cold extruded) 40 to final gauge.

While individual properties such as yield strength, resistance to stress relaxation and electrical conductivity are individually important to characterizing a copper alloy suitable for use as an electrical connector, a holistic value integrating multiple relevant properties is more useful. This

holistic approach may utilize Quality Function Deployment, QFD. QFD is a methodology for developing a design quality aimed at satisfying the customer and then translating the customer's demand into design targets to be used throughout the production phase. The customer is surveyed to identify those properties most important to the customer's application and to rank the relative importance of each of those properties. The customer also identifies a range of values for each of the desired properties from a "disappointing" minimally acceptable value to "desirable" up to "exaggerated".

QFD is more fully described in two articles by Edwin B. Dean, Quality Function Deployment from the Perspective of Competitive Advantage, 1994 and Comprehensive QFD from the Perspective of Competitive Advantage, 1995.

Both articles are downloadable at <http://mijuno.larc.nasa.gov/dfc/qfd/cqfd.html> and incorporated by reference in their entireties herein.

Table 1 recites a list of properties, ratings and ranges for a copper alloy intended for use in automotive applications while Table 2 recites similar properties,

ratings and ranges for a copper alloy for use in a multimedia application. The "rating" is on a scale of 1 to 10 with 10 meaning the property value is of utmost value while 1 meaning the property value of minimal

5 value.

90° bend and 180° bend of equal relative importance, both (.65x.5=.325).

5 90° bend value utilizing V-block method, 180° bend value utilizing forming punch method.

The copper alloys of the invention are capable of achieving a QFD value in excess of 50 (desirable) both for automotive and industrial applications and for multimedia applications indicating that a customer would
5 find the subject copper alloy acceptable for both applications.

While described above in terms of copper alloy strip formed into electrical connectors, the alloy and processing of the invention are equally suitable for
10 forming into leadframes. Leadframes require good bend properties as the outer leads are bent at a 90° angle for insertion into a printed circuit board. The fine grain structure and absence of coarse particles makes the alloy amenable to uniform chemical etching, a
15 process used in leadframe formation.

While described above in terms of a copper alloy formed into a strip, the alloy and processing of the invention are equally suitable for forming rod, wire and sections for electrical applications. Prerequisite high
20 stiffness is provided by the high Young's Modulus, around 140 GPa, of the alloy. Higher electrical conductivity and higher strength may be achieved, at the expense of bendability, by extending intermediate rolling or drawing to up to 98%, by thickness, and by
25 adding one or more intermediate anneals at a temperature of from 350°C to 900°C for from 1 minute to 6 hours.

The advantages of the copper alloy of the invention will become more apparent from the examples that follow.

EXAMPLES

Example 1

A copper alloy having a nominal composition of 0.55% chromium, 0.10% silver, 0.09% iron, 0.06% titanium, 0.03% silicon, 0.03% tin and the balance copper and inevitable impurities was melted and cast into an ingot. The ingot was machined and hot rolled at 980°C, quenched and processed to a strip thickness of 1.1 mm. The strip was cut into a piece of about 300 mm in length, immersed into a molten salt bath at 950°C for 20 seconds, and then quenched in water to room temperature (nominally 20°C). The surfaces of the cut strip were milled to remove surface oxides and then cold rolled to an intermediate gauge of 0.45 mm and heat treated at 470°C for 1 hour followed by heat treating at 390°C for 6 hours. After that, the strip material was rolled to a final gauge of 0.3 mm and subjected to a stress relief anneal at 280°C for two hours.

The final product showed the following properties:

Yield strength = 84 ksi (580 MPa);

Modulus of elasticity = 145 GPa;

90° bending radius $0 \times t$ (V-block method,
micrographic inspection revealed no cracks);

180° bending radii $0.8 \times t$ (form punch method
micrographic inspection revealed no cracks);

Stress relaxation -

6% loss of stress following 100°C exposure for
1000 hours,

13% drop in stress following exposure to 150°C
for 1000 hours, and

22% loss of stress following 200°C exposure for
1000 hours;

5 Ultimate tensile strength 86 ksi (593 MPa); and
Electrical conductivity 79% IACS.

This alloy had a QFD rating for automotive and
industrial applications of 54, see Table 12 and for
multimedia applications 64, see Table 11.

10

Example 2

Seven copper alloys having the compositions
identified in Table 3 were melted and cast as 10 pound
ingots into steel molds. After gating, the ingots had a
15 size of 4"x4"x1.75". The cast ingots were heat-soaked
at 950°C for two hours and then hot rolled in six passes
to a thickness of 0.50" and water quenched. Following
trimming and milling to remove oxide coating, the alloys
were cold rolled to a nominal thickness of 0.045" and
20 solution heat-treated at 950°C for 20 seconds in a
fluidized bed furnace followed by a water quench.

The alloys were then cold rolled to a 60%
reduction, by thickness, in a sequence of several passes
to a thickness of 0.018" and then subjected to a double
25 aging anneal consisting of a first static anneal at 470°C
for one hour followed by a second static anneal at 390°C
for six hours. This heat treatment hardened the alloys
while increasing conductivity over the cold rolled
values without recrystallizing the microstructure. The

Alloys BT and BU were processed essentially the same way as alloys O and E except that the aging treatment consisted of two-stage anneal with a first stage of 470°C for one hour and a second stage of 390°C for six hours. The tensile strength and conductivity properties were measured in the as-aged condition and, as shown in Table 6, showed a decrease in stress relaxation (increase in stress relaxation resistance) with a silver addition at a 0.5% chromium level.

Example 3

Tables 7A and 7B show how both the composition and processing of the invention lead to improved bends. As shown in Table 7A, when processed with a solution heat treatment (SHT) the alloy of the invention J310 had isotropic bends while the silver-free control alloy J306 had somewhat anisotropic bends. Control alloy K005 when processed with bell anneals (BA) with intervening cold rolling reductions, had anisotropic and poorer bends. Bend evaluation of alloys J306, J310 and K005 in Table 7A was by the mandrel method which has been found to give at least 0.5 higher bend values than by the V-block method.

When alloys K007 and K005 were processed by the steps of homogenization at between 850°C and 1030°C for from one to 24 hours, hot rolling at a temperature of between 600°C and 1000°C and then quenching at a cooling rate of between 50°C and 1000°C per minute. These steps were followed by cold rolling up to 99% with one or two intervening bell anneals at a temperature of 350°C to 500°C for up to 10 hours (conventional BA process).

Table 7B shows that with the conventional BA process, the silver containing alloy K007 had better bends. Bend evaluation of the alloys reported in Table 7B was by the V-block method.

Table 7B shows that better bends were obtained for alloys of the invention, K007 and K008, compared to commercial alloy K005 when both are processed either by a conventional bell anneal (BA) process or by a solution heat treatment (SHT) process. Better bend formability and isotropic values are obtained by the new process (SHT) relative to the conventional BA process.

5

TABLE 7A

Calculations supporting the rating as a function of the measured value illustrate that the achievement of the requirements by different alloys or tempers should be measurable.

5 For this purpose s-shaped mathematical functions can be used. The rating of the achievement should be low, e.g. 5%, at the disappointment limit. Close to the desirable property the rating should reach about 50% and should reveal a steep increase or decrease with small
10 variations in the property measured. At the exaggeration limit the requirements are over-fulfilled. The rating should reach 95%. Further improvements can not improve customer satisfaction too much. Variations in property should only result in small variations of
15 the rating.

We use a scaled arc tan-function $w(f(x))$ for this purpose. The function is bound to a lowest (x_{\min}) and highest value (x_{\max}) of the property of interest. Here the ratings $w(f(x))$ are set to zero or 100%
20 respectively. Between these values for the rating $f(x)$ two points given will shape the s-function.

$$f(x) = 50 + (100/B) \cdot \arctan (c1 \cdot (x + c2))$$

25 The constants $c1$ and $c2$ are calculated from the two ratings set by $(x_1, f(x_1))$ and $(x_2, f(x_2))$. These settings being made by decision about the suitable characteristic of the rating.

30 $w(f(x)) = w(f(x_{\min})) + (w(f(x_{\max})) - w(f(x_{\min}))) \cdot (f(x) - f(x_{\min})) / (f(x_{\max}) - f(x_{\min}))$

Table 10 illustrates that a copper alloy having the nominal desirable properties as recited in Table 2 has a QFD rating of 51. Table 11 illustrates that the copper alloy of Example 1 has a QFD value of 64 for multimedia applications and Table 12 illustrates the alloy has a QFD value of 54 for automotive and industrial applications.

It is apparent that there has been provided in accordance with this invention a copper alloy characterized by high strength and high electrical conductivity that is particularly suited for electrical connector applications that fully satisfies the objects, means and advantages set forth hereinbefore. While the invention has been described in combination with specific embodiments and examples thereof, it is evident that many alternatives, modifications and variations will be apparent to those skilled in the art in light of the foregoing description. Accordingly, it is intended to embrace all such alternatives, modifications and variations as fall within the spirit and broad scope of the appended claims.
